

Be AND SHELL STARS OBSERVED WITH THE THIRTEEN-COLOR PHOTOMETRIC SYSTEM. II.

W.J. Schuster and J. Guichard

Instituto de Astronomía
Universidad Nacional Autónoma de México

Received 1984 May 15

RESUMEN

Se presentan medidas fotométricas individuales de 13-colores para 89 estrellas Be y estrellas con envoltante (shell stars) observadas en el observatorio en San Pedro Mártir. Se discuten procedimientos observacionales, técnicas de reducción y problemas de transformación para varios colores. 22 estrellas definitivamente muestran variabilidad fotométrica usando estos nuevos datos.

ABSTRACT

Individual 13-color photometric measurements for 89 Be and shell stars observed at the observatory at San Pedro Mártir are presented. Observing procedures, reduction techniques and transformation problems for several colors are discussed. 22 stars show definite photometric variability using this new data.

Key Words: STARS-Be – 13-COLOR PHOTOMETRY – VARIABILITY

I. INTRODUCTION

In Schuster and Alvarez (1983, Paper I) average 13-color data for 86 Be and shell stars as well as a discussion of the spectral-energy changes of the 16 most variable stars were presented. In that paper, and in Alvarez and Schuster (1981, 1982), the usefulness of the 13-color photometric system for studying Be and shell stars has been shown. The 13 filters range in effective wavelength from 3370 Å to 1.1 μ m and provide good measures of the stars' ultraviolet, visible, red and near-infrared continuum variabilities. There are photometric indices which span the Balmer and Paschen jumps and which give the slopes of the Balmer, Paschen and Brackett continua while avoiding most of the strong line features in the spectra of early-type stars.

In addition, intrinsic 13C colors have been derived for normal B stars (Schuster 1984a) providing a basis for the study of color excesses of Be and shell stars. Methods for separating the intrinsic color excesses from interstellar reddening are being studied and once completed will allow more detailed analyses of the physical emission processes in the stellar envelopes. Preliminary results (Alvarez and Schuster 1981) indicate that the stars are most variable at wavelengths where the intrinsic excesses are largest. Probably the same processes, such as H^- free-free and bound-free emission and Balmer and Paschen continuum emission, are responsible for both the intrinsic excesses and variability.

Also, in Schuster (1984a) it has been shown that the 13C system can be used to obtain intrinsic colors, reddening values, approximate MK spectral types, effective temperatures, absolute visual magnitudes, surface gravities, distances and angular and linear diameters for normal B stars. With only a few assumptions most of these techniques can be applied to Be and shell stars. More detailed descriptions of the 13C photometric system and its uses are given in Johnson, Mitchell, and Latham (1967), Mitchell and Johnson (1969), Johnson and Mitchell (1975), and Schuster (1982a).

In this paper are presented new, individual observations for 89 Be and shell stars made during the years 1980 to 1983. 79 stars were observed using the red (6RC) photometer with the original filters and 64 with the new filter set No. 1. For 27 stars the 13C photometry has been completed by observing also with the blue (8C) photometer using the new filter set No. 1. However, the 6RC and 8C observations were not made simultaneously; the 8C data was taken in March 1981 and April 1983 and the 6RC data during several observing runs from September 1980 to April 1983.

II. OBSERVING AND REDUCTION TECHNIQUES

The observing procedures were those of Schuster (1982a). Generally the 84-cm and 1.5-m telescopes of

the San Pedro Mártir observatory and the D.C. amplifier No. 1 were used for these observations. For two nights of 6RC observing (19/20 and 20/21 September 1982) the amplifier No. 4 was substituted. Many of the β Lyrae (BS 7106) observations and three nights of 8C observations (23/24, 24/25 and 27/28 March 1981) were made with the 2.12-m telescope. The original photometers and photomultipliers were always employed, and until February 1981 also the original filters. Starting in March 1981 the original filters were replaced by the new filter set No. 1.

Data taken with the original filters were reduced totally and easily using the procedures of Schuster (1982a). The preliminary reductions of the data observed with the new filters also followed these precepts, but the final reductions were carried out according to the ideas discussed in Schuster and Guichard (1984), forcing the mean color coefficients from their Table 3. In the reductions of the 8C photometry the standard stars were used to calculate solely the zero points of the transformation and the corrections to the mean extinction. For the 6RC data only the standard stars and color coefficients measured at the same high voltage as the program stars were included in the re-reductions. For the years 1981 and 1983 mean annual atmospheric extinction values were used, but during 1982 the extinction was more variable, and the nightly extinction values of the preliminary reductions were forced in the final 6RC solutions.

The above iterative process was necessary since the natural photometric systems of several of the new 13C colors, namely $(33-52)$, $(40-52)$ and especially $(37-52)$, did not transform linearly onto the standard 13C system. In Schuster and Guichard (1984) an analysis of the transformation residuals for the new 13C filter set No. 1 has been made for the early-type stars as a function of the stellar effective temperatures and surface gravities (or luminosities). These analyses were based upon the multiple, independent observations of the primary 13C standard stars (Table 1, Schuster 1982a) used to reduce the individual nights and upon the observations of 33 secondary standard stars from the lists of Johnson and Mitchell (1975) and Schuster (1976, 1979 and 1984b) re-observed during two nights of April 1983. The Be stars were not included.

For each primary or secondary standard star the transformation residuals from the better photometric nights were averaged. Each residual was the difference between the standard or old 13C value and a new value measured with the new filters and reduced iteratively as described. For the B stars equations of the form $\langle \text{Res} \rangle = a\ell + b\tau + c$ were solved by least-squares, where $\langle \text{Res} \rangle$ are the average residuals, and $\ell = (37-45) - 0.467(40-58)$ and $\tau = (35-40) - 0.304(40-58)$ are the reddening-free luminosity and temperature indices of Schuster (1984a), respectively. For the spectral and luminosity range of the classical Be stars, B0-B9 and V-III,

the following solutions give the best fits to the transformation residuals:

- (a) For $33-52$: $a = 0$, $b = -0.0202$, $c = -0.0110$,
- (b) For $37-52$: $a = 0$, $b = -0.0699$, $c = -0.0377$, and
- (c) For $40-52$: $a = 0$, $b = +0.0328$, $c = +0.0178$.

(This is solution 5 of Schuster and Guichard 1984). More general solutions which include A-type and supergiant (Ib) stars but which do not fit as well the lower luminosity B-type stars are the following:

- (a) For $33-52$: $a = -0.0237$, $b = -0.0031$, $c = -0.0099$,
- (b) For $37-52$: $a = -0.1322$, $b = 0.0247$, $c = -0.0309$, and
- (c) For $40-52$: $a = +0.0417$, $b = -0.0064$, $c = +0.0165$.

Residuals, or corrections, calculated using the above coefficients should be added to the 8C values given below in Table 1 to more nearly transform onto the standard 13C system.

In Figures 1 and 2 the $(37-52)$ values of 16 Be stars observed with the new filters are plotted without and with the corrections of the first solution above, respectively, and against their original $(37-52)$ values (Schuster and Alvarez 1983). The photometrically most varia-

Fig. 1. The average values of $(37-52)$ observed with the new 13C filters (set No. 1) are plotted against the original $(37-52)$ values of Schuster and Alvarez (1983) for 16 Be stars. The photometrically most variable Be stars of Alvarez and Schuster (1982) have been excluded. The dashed line has a slope of unity, and the solid line is a least-squares fit to the data.

Fig. 2. The same as Figure 1 except that the new $(37-52)$ values have been corrected using the first solution given in the text. This is the solution number 5 of Schuster and Guichard (1984) which corrects for the transformation residuals of normal B-type stars, luminosity classes V-III.

ble Be stars from Alvarez and Schuster (1982) have not been included. The emission lines only slightly affect the $(37-52)$ color and the ℓ and τ indices, even for the strongest emission-line stars (Hubert-Delplace and Hubert 1979), and so the transformation corrections for $(37-52)$, calculated using normal B stars, should improve even the data for Be stars. In Figures 1 and 2 the dashed lines have slopes of unity, and the solid lines show least-squares adjustments to the data. Obviously, the agreement between photometric values taken with the original and new filters is better when the above corrections are applied.

The $(33-52)$ color also is only slightly affected by the emission lines, but $(40-52)$ somewhat more. With only one exception (the 63 filter) the wavelengths and band-passes of the original 13C filters were chosen such that they avoid the principal emission lines of the Be stars, $H\alpha$, $H\beta$, and $H\gamma$. All other emission lines are weak compared to these. $H\delta$ emission, if any, enters into the 40 measurement, the He I line at 5876 Å affects slightly the 58 photometry, and weaker iron and other emission lines contribute to a small degree to other filter measures (Hubert-Delplace and Hubert 1979). The transformation corrections for $(33-52)$ and $(40-52)$ are smaller than those of $(37-52)$ and cannot be accurately tested with only a small sample of Be stars. Also, $(33-52)$ measures the Balmer jump which is one of the more variable features of the Be and shell stars (Schuster and Alvarez 1983).

The Be star observations were not included in the solutions for the transformation residuals due to the

Fig. 3. The $(52-63)$ values observed with the new 13C filters are plotted against the original $(52-63)$ values of Schuster and Alvarez (1983). Be stars with strong emission lines (Hubert-Delplace 1976) are shown as triangles, the photometrically more variable Be stars (Alvarez and Schuster 1982) by pluses, and other Be or shell stars by circles.

possible photometric variability of most Be stars (Feinstein and Marraco 1979; Alvarez and Schuster 1981). In addition, filters that measure spectral regions with emission lines might have transformation problems different from those detected for the normal B stars. For the colors $(33-52)$, $(37-52)$ and $(40-52)$ such differences have not been detected with the present data, and the given corrections should be applied to the Be star photometry. However, for one other color the Be stars do have a transformation problem unlike the normal B-type stars.

In Figure 3, $(52-63)$ values observed with the new filters are plotted against the original values. The original 63 filter is a long-pass glass filter, and the long wavelength side of the filter-detector response function is defined strictly by the falling sensitivity of the 1P21 detector. The 10% level of the response function occurs approximately at a wavelength of 6700 Å. The new 63 filter is an interference filter which cuts more sharply on the long wavelength side; the 10% level falls at about 6450 Å. For Be stars with strong $H\alpha$ emission, which are not uncommon, the original $(52-63)$ values contain significant effects of the line emission while values measured with the new 63 filter do not. This is clearly seen in Figure 3 for several Be stars classified as having strong emission lines (Hubert-Delplace 1976). This type of transformation problem is not correctable using only our 13C continuum photometry, but one should be aware of the effect in this new data. The new 63 filter gives a cleaner measure of the stellar continuum radiation of Be stars than does the original filter.

III. THE DATA

Tables 1, 2 and contain our most recent 13C observations of Be stars made during the years 1980-1983. Table 1 holds the reduced photometry from the new 8C filters, Table 2 from the old 6RC filters and Table 3 from the

new 6RC filters. The transformation corrections should be calculated and added to the (33-52), (37-52) and (40-52) values of Table 1. Observations taken with the new 6RC filters transform well onto the standard 13C system without correction (Schuster and Guichard 1984).

The columns of Tables 1, 2, and 3 are self-explanatory. Two lines are used for each night's observation, and 2 430 000 should be added to the 'Julian Date' to derive the actual Julian Date of the observations.

In column 8 of Tables 1, 2 and 3 it is seen that a few of the Be stars were observed at the end of an observing season, at larger than normal air masses ($2.0 < X < 3.0$). However, Schuster (1982a) and Schuster and López (1976) have demonstrated that it is not uncommon to obtain good photometric precision to three air masses at the observatory at San Pedro Mártir. The large air-mass observations of Tables 1, 2 and 3 are in fact in good agreement with other independent observations.

In Table 4 are listed Be stars that are photometrically variable according to this new data. Columns 1 and 2 give the HD and Bright-Star (Hoffleit and Jaschek 1982) numbers of the stars respectively, column 3 indicates the degree of variability according to this latest comparison, column 4 the colors and magnitudes which are most variable, and column 5 our previous assignment of variability (Schuster and Alvarez 1983). In columns 3 and 5 "PV" means possibly variable, "V" means variable and "V++" very variable. The new observations were compared within each table, between Tables 2 and 3, and with the values of Schuster and Alvarez (1983).

Quantitatively, variations greater than approximately ± 0.05 mag lead to a PV classification, greater than approximately ± 0.08 mag to V, and greater than or equal to ± 0.15 mag to V++. The criteria of Schuster and Alvarez (1983; also Alvarez and Schuster 1981) were slightly different. The 58 magnitude of 6RC photometry (the 58-110) color, and observations made at large air masses were given less weight than the other magnitude and colors in the detection of variability. Generally, an assignment of variability did not result from only single measurement but from several disparate values in more than one magnitude or color. Six new Be stars in the category V++ have been identified: BS 2817, BS 2921, BS 6984, BS 7565, HD 206773 and HD 218674. Altogether 22 Be or shell stars are seen to be variable according to this new data.

In column 4 of this last table four different types of photometric variability can be distinguished. For 80 observations changes in the Balmer jump, colors (33-52 and (35-52), and variations in the visible magnitudes 52 and 58, are the largest and most frequent. In the red and near-infrared, the energy distributions vary most often at the wavelengths of filters 80 and 86 due either to Paschen continuum emission or to H⁻ processes (Schild 1978). Finally, another type of near-infrared

TABLE 4
VARIABLE Be AND SHELL STARS

Star		Variability	Colors and Magnitudes Most Variable	Previous Variability

18674	...	V++	58	PV

riability, which increases with wavelength having its maximum fluctuation at the 1.1 μ m limit of the 13C photometry, is common.

The authors are especially grateful to the personnel of the Observatorio Astronómico Nacional, at San Pedro Mártir, for its considerable support during the observations published here. G. Sánchez, R. Murillo, C. Valle, M. Murillo, A. Ibarra, M.A. García, A. Ojeda and E. López deserve special thanks. We are greatly indebted to the Centro de Investigación Científica y Educación Superior de Ensenada that generously made available computing facilities for reducing the photometric data. We also thank C. Harris for help in the preparation of the manuscript.
