RESUMEN

Se presenta la fotometría fotoeléctrica diferencial para las estrellas variables del tipo delta scuti HR 4684 y HD 106103. Mediante una recopilación de fotometría fotoeléctrica uvby- β de 69 estrellas en la dirección del cúmulo abierto en Coma Berenices se determina la membresía de las estrellas al cúmulo. El enrojecimiento y la distancia encontrados son E(b-y)=0.002 mag y 81.75 pc, respectivamente. Se determina además la temperatura efectiva y la gravedad superficial de las estrellas miembros. Se encuentra una edad del cúmulo de 5×10^8 años. No se encuentran diferencias físicas entre las estrellas pulsantes y las estrellas dentro de la zona de inestabilidad. Se determinan fotométricamente algunas estrellas como pertenecientes a las clases Ap.

ABSTRACT

Differential photoelectric photometry of the Delta Scuti stars HR 4684 and HD 106103 is presented. Membership of these stars to the cluster is established through a compilation from the literature of uvby- β photometry of 69 stars in the direction of Coma Berenices. Reddening and distance are determined to be of E(b-y) = 0.002 and 81.75 pc, respectively. An age for the cluster of 5×10^8 yr is derived by comparison with theoretical isochrones. Values of $\log T_{eff}$ and $\log g$ are determined for each member star to the cluster. No significant physical difference is found between the variable stars and others with the same physical characteristics. Determination of several Ap stars is established.

Key words: GALAXY-OPEN CLUSTERS AND ASSOCIATIONS — STARS-VARIABLES- δ Scu — TECHNIQUES-PHOTOMETRIC

1. INTRODUCTION

This is the third paper of a series dealing with galactic clusters. The goals of this project are to fix membership of each star in the cluster, as well as to determine their effective temperature, surface gravity and metal abundance in order to try to

¹ Based on observations collected at the Observatorio Astronómico Nacional, San Pedro Mártir, B.C., México.

distinguish the differences that make some stars pulsate, whereas others, with the same effective temperature and gravity, do not. The program is designed to both discover new pulsating stars and to study those which are already known as members of the cluster.

On this occasion the open cluster in Coma Berenices was selected because HR 4684, the first Delta Scuti type variable found in open clusters (Breger & Sanwal 1968) and HD 106103, another

129

130 PEÑA ET AL.

Delta Scuti star discovered by Jacksich (1972) are located in its direction. The open cluster in the constellation of Coma Berenices is one of the nearest to the Sun (d = 80 pc, Abt & Levato 1977). It is unique because of its high galactic latitude ($b = 84.1^{\circ}$, $\ell = 221.1^{\circ}$, Cameron 1985), which is very near the galactic north pole. According to Abt & Levato (1977), the earliest spectral type of member stars is A2V, and the cluster has been assigned an age of 5×10^8 yr.

The majority of previous papers on this cluster have reported that there is no interstellar reddening in its direction; for example, Cameron (1985) and Hagen (1970) have reported that E(B-V)=0. Cameron (1985) determined its metallicity to be [Fe/H]=-0.063.

Many reports on the spectroscopic and photometric investigations of this cluster exist in the literature. Mendoza (1963, 1967), Abt & Levato (1977) and Deluca & Weiss (1981) among others have carried out spectral classification of a few members. On the other hand, most of the photoelectric photometry has been obtained only in the UBV system; for example, Johnson & Knuckles (1955); later Argue & Kenworthy (1969) studied possible new faint members. However, there is only one published paper (Crawford & Barnes 1969) and, to our knowledge, one Master's thesis (Díaz 1991), which includes uvby-β photometry. The first authors observed only 38 stars and a distance modulus of 4.5 mag was reported, although Cameron (1985) later assigned a value of 4.65 mag. The work by Díaz (1991) increased the sample to 69 observed stars in the Stromgren

The problem of membership of the stars to Coma has been studied since 1938 when Trumpler obtained a list of 37 members based on proper motions, radial velocities, and the position in the HR diagram for each star in the direction of said cluster. More recently, several other studies have been carried out with proper motions (for example, Covas 1981; Eggen 1973), although it is not enough to assign membership in the Coma Berenices cluster based on this criterion alone. In the present paper, differential photoelectric photometry in HR 4684 and HD 106103 is presented along with the previously mentioned compilation of photometric values of stars in the direction of Coma Berenices in the $uvby-\beta$ system to provide a mean to determine membership for each star. The basic calibrations of Nissen (1988) have been utilized for the A and F stars in a prescription that closely resembles that of Crawford (1975, 1979). For the B type stars, Crawford's studies have been supplemented by those of Balona & Shobbrook (1984) and Shobbrook (1984). A numerical estimation for establishing membership in a cluster has been utilized (Peña

et al. 1993), and new values of distance and reddening have been calculated. Furthermore, for each member the effective temperature and surface gravity are derived. An age estimate of the cluster is done through direct comparison with theoretical evolutionary tracks.

2. OBSERVATIONS

The first observing campaign was designed to determine the periods of pulsation of HR 4684. Thus, a simultaneous observing season was planned at two observatories located at different longitudes, namely, the Ege University Observatory, Turkey, and the Observatorio Astronómico Nacional, at San Pedro Mártir, México (hereafter SPM). The dates of observation, the telescopes employed, their location and instrumentation have been summarized in Table 1.

In México, two telescopes were used: the 150-cm and the 84-cm. A single-channel photometer with a dry-ice-cooled 1P21 photomultipler was utilized on each. Each measurement consisted of five tensecond integrations of each star and one ten-second integration of the sky which was subtracted from the average star integration. The photometric values reported are the magnitude differences between the variable star and the magnitude value of the comparison star interpolated to the time of observation of the variable.

In Turkey, the observations of HR 4684 were made at the Ege University Observatory. An unrefrigerated EMI 9781 photomultiplier with a Johnson V filter and a 48-cm Cassegrain reflector telescope were utilized. Correction for atmospheric extinction was carried out.

In this campaign, the sequence of observation was HR 4684 and BD 26°2329, as a comparison star.

The star BD 26°2324 was observed at SPM as a check star. A continuation of this campaign was carried out one month later with the 150-cm telescope at SPM observatory through the 52 filter of the 13-color system (Johnson & Mitchell 1975). A second

observing run utilizing differential photometry was carried out in 1984 at SPM observatory. During this latter season two Delta Scuti type stars HR 4684 and HD 106103 were observed with the b filter of the Stromgren system. The comparison stars for each

132 PEÑA ET AL.

were respectively, BD 26°2329, which had been used before, and BD 28°2084. Each was of about the same magnitude and within 15' of the variable star.

Tables 2, 3, 4 and 5 list the observation time in HJD and the variation in magnitudes of HR 4684 with filters V, B, 52 and b, respectively; Table 6 gives the values of HD 106103 with the b filter. To the time shown, the large figure of the real Julian Heliocentric Date, presented in Table 1, has been

subtracted. Errors in each figure are ± 0.0014 d in time and ± 0.002 mag in the photometry. The listed values are shown schematically in Figures 1, 2, 3 and 4.

Since, without planning to do so, these seasons practically coincide with a separate observing campaign by Paparo & Kovacs (1984), communication was started between the observers; the period analysis of the three campaigns is presented separately (Paparo et al. 1993)

4. ANALYSIS

The multicolor photometric data was compiled from two sources: Crawford & Barnes (1969) and

Díaz (1991). Both sets had a subset of twenty stars in common which were employed to compare and establish the results of both authors.

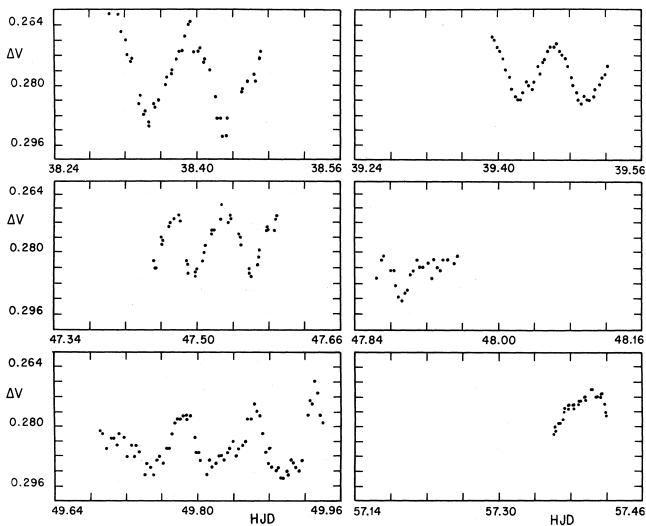

Fig. 1. Variation, in magnitudes, of HR 4684 in the V filter of Johnson's system.

Equally, for comparison purposes, the apparent magnitudes provided by several authors (Trumpler 1938; Mendoza 1963; Johnson & Knuckles 1955, and Argue 1963) were employed.

The values of the V magnitude reported by Díaz (1991) were compared with the aforementioned magnitude values. The rms of the differences with Trumpler (1938) was of 0.018 mag with 20 pairs; with Mendoza (1963), of 0.03 with 37 pairs; with Johnson & Knuckles (1955) of 0.018 with 20 pairs and Argue (1963) of 0.03 with 12 pairs. In view of the differences, the photometric values reported by Díaz (1991) were retained.

Equally adequate was the comparison of Díaz (1991) with the reported values of Crawford & Barnes (1969) in the color indexes b-y, m₁ and c₁. For the sample of twenty stars in common, the rms of the differences were less than the errors reported

by Díaz (1991) in his transformation to the standard system. He states: "The photometric values derived for the standard stars have standard deviations in V_t , V_t , and V_t of 0.008, 0.006, 0.006, 0.007, and 0.007 mag, respectively. The reported values for V_t and V_t were calculated for V_t of 0.409 mag". In view of this, the values of these indexes reported by Díaz (1991) were used and, for those twenty stars in common, the final assumed values were the mean values.

A different approach was taken for the β index since a systematic difference was found in the two sets. A linear relation was established between them by means of the equation $\beta(\text{Díaz}) = 0.117 + 0.951 \times \beta(\text{Crawford})$ with a correlation coefficient of 0.9958. The remaining values of Díaz (1991) were transformed accordingly.

The final list of the compiled data, in decreasing

values of β , is presented in Table 7. Using it, determination of the reddening, distance and physical parameters to each one of the stars can be accomplished.

Several methods for determining the membership of stars in a cluster are known. One of the most used, although one of the roughest, is that of fitting the main sequence to the color-magnitude and color-color diagrams (Trumpler 1938). The most accurate methods are those which make use of the proper motions or radial velocities (Vasilevkis, Klemola, & Preston 1958). Another method, which is employed in the present paper, is based on the determination of the distance through empirical calibrations of M_V and reddening via the $uvby-\beta$ photometry.

4.1 DM Determination

The determination of the unreddened distance modulus DM is the basic physical quantity on which the photometric membership probability is based. This method of evaluating DM for A and F type stars

^a CB = Crawford & Barnes 1969. D = Díaz 1992.

has been used previously by Peniche et al. (1990). This work has also been carried out considering the previous papers of Crawford and his co-workers (1975, 1979) and of Nissen (1988).

In 1975 Crawford defined those stars that satisfy $2.59 < \beta < 2.72$ mag, $\delta c_1 < 0.28$ mag, and that are not B stars, as spectral class F. He determined empirical calibrations for M_V and $(b-y)_0$ as well as for the metallicity, [Fe/H]. On the other hand, Crawford (1979) defined A-type stars as those which satisfy $2.72 < \beta < 2.89$ mag, $\delta c_1 \le 0.28$ mag, and which are not B stars. Again, he determined empirical calibrations for the visual absolute magnitude and the color index $(b-y)_0$. Once M_V and $(b-y)_0$ are known for the A and F stars, DM can be calculated.

Using the β criterion alone for stars of type B, a determination of which stars are type B is impossible since the same value of β can be obtained for A and F stars as well as for B stars. Hence, a main sequence B-type star can be defined

photometrically if it satisfies the conditions: i) 1.0 < [c₁] < 0.2 mag and, ii) 0.145 < [m₁] < 0.07 mag. This definition has been obtained from the [c₁]-[m₁] diagram of Stromgren (1966) which unambiguously determines the spectral type of the main sequence stars.

In order to determine DM for stars of spectral class B, Crawford (1978) obtained empirical calibrations for $(b-y)_0$ and M_V . Later, Hilditch, Hill, & Barnes (1983) modified this calibration slightly for $(b-y)_0$, which is valid up to the A2V stars.

The visual absolute magnitude is calculated using the calibration determined by Balona & Shobbrook (1984) which includes an evolutionary correction. Finally, using the evaluated values of V_0 and M_V , the distance modulus, DM, can be determined for each star of spectral type B or early A.

With the above definitions, a separation between the classes B and A and F can be carried out, and a direct evaluation of DM can be done. 138 PEÑA ET AL.

5. RESULTS AND DISCUSSION

5.1 Membership

One of the most important goals of this project is the determination of the physical membership in clusters while discarding field stars. The prescription using uvby- β photometry consists basically of fitting a normal curve to a distance histogram. Once the Gaussian distribution function has been fitted, the area under the curve in a given interval represents the probability that a corresponding random variable can be found in this interval.

Utilizing the previously described criteria with the photometric data in Table 7, the unreddened parameters are determined for each star and, hence, a membership probability can be assigned.

Figure 5 shows the histogram, in distance, of the cluster for those stars in the direction of Coma Berenices. However, it is obvious that the limits suggested by both A and F stars separately or together between 70 and 90 pc are the limits of the cluster.

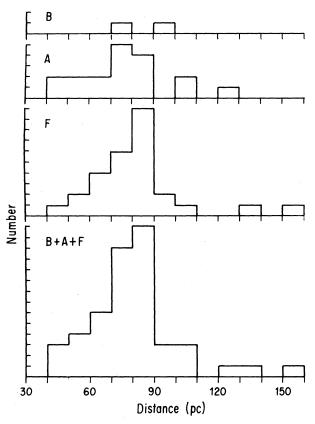

Fig. 5. Histogram of distance for those stars for which, through the compiled data in the $uvby-\beta$, allowed the distance determination.

Table 8 lists the reddening, E(b-y), and the unreddened distance modulus determined for the A and F stars for those stars that were finally determined to be cluster members in Coma Berenices. The first column gives the identifier used by Trumpler The second to eighth columns list the (1938).reddening, the unreddened indexes $(b-y)_0$, c_{1_0} , and m_{10} , the absolute magnitude, distance modulus and distance, in pc, and the metal content [Fe/H], respectively. It is worth mentioning that, except for only one star, TR 96, the membership to the cluster assigned in this work coincides absolutely with the probability assigned by Trumpler (1938) which is based on three criteria: proper motions, location in the HR diagram and radial velocities.

5.2 Distance, Reddening and Metallicity of Coma Berenices

In the present paper, an average unreddened distance of 81.75 pc with a standard deviation of ± 5.89 pc has been found. This figure corresponds to an average distance modulus of 4.56 mag between the limits 4.40 and 4.71 mag. The generally accepted value, in distance, of 80 pc lies within this range.

The average color excess for this cluster is E(b-y) 0.002±0.01 mag or, correspondingly, $E(B-V) = 0.003\pm0.014$ mag. This latter figure has been obtained considering the relationship E(b-y) = 0.7 E(B-V) of Crawford & Mandwewala (1976). This reddening is in good agreement with other studies which, like Cameron (1985) and Nissen (1980), conclude that there is practically no interstellar extinction at 80 pc in the direction of the galactic north pole.

The metallicity [Fe/H] of the cluster has been determined using the calibration of Nissen (1988), which has already been used in Peña et al. (1993). The derived value determined in the present paper, from a sample of 16 F type stars, -0.030 ± 0.078 , does seem to be in fair agreement with the most widely accepted value of [Fe/H] = -0.063, which was determined by Cameron (1985) or with the value proposed by Nissen (1980) who determined $[Fe/H] = -0.003\pm0.02$ from 18 stars of spectral type F. However, if only two stars are not considered in the evaluation of the average metallicity, TR90 and TR114, exclusion that can be justified because their metallicity is discordant with the mean and beyond the values of the standard deviation, the mean [Fe/H] for the member stars from a sample of 14 is -0.007 ± 0.052 , much more in agreement with the reported values in the literature.

5.3 Effective Temperature and Surface Gravity

In order to determine T_{eff} and log g for the A and F member stars to the cluster, the grids

developed by Relyea & Kurucz (1978) have been used with the unreddened values for each one listed in Table 8 (see Figure 6). Using the grid c_0 versus $(b-y)_0$ (Figure 19 in Relyea & Kurucz 1978), the A and F member stars have been located using the values listed in Table 8 (see Figure 6). The effective temperatures for the hottest member stars, TR107, TR130 and TR183, for which uvby- β photometric data were available in the Coma cluster lie below 3500 K, whereas the surface gravity varies in the range log g between 3.0 and 4.5.

For the Am and Ap stars which are members, he values of $(b-y)_0$ and c_0 have been calculated considering the average reddening determined for the cluster, $E(b-y) = 0.002\pm0.01$ and $E(c_1) = 0.0004\pm0.00020$, where the relation $E(c_1) = 0.20$ E(b-y) of Crawford & Mandwewala (1976) has been used.

5.4 Age

The age of the cluster in Coma Berenices has been calculated from the evolutionary models of VandenBerg (1985). If the metal abundance, which roughly agrees with that reported by Cameron 1985) and which was determined in the present paper, is considered, the derived age is 5.0×10^8 yr, in agreement with the value reported by Abt

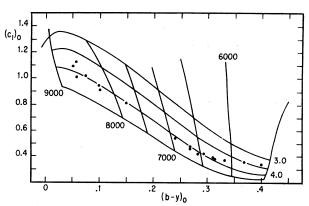

Fig. 6. Location of the member stars of the Coma Berenices cluster in the theoretical grids of Relyea & Kurucz.

& Levato (1977). A similar age is derived if the isochrones of Iben (1985) are employed.

5.5 Ap Stars

The spectral classification of the stars in Coma Berenices has been known for a long time, since the publication of Trumpler's (1938) pioneer work. From the 71 spectral types he assigned out of the 200 photometrically observed stars, he lists only

two as SrII peculiars, and he classified them with a special notation. In the same work, he lists some stars that appeared to have double spectra, or that had the same peculiarity found in the two aforementioned Sr stars. More recently, these classifications have been used as standards for testing new methods for the photometric classification of Ap stars, Cameron (1966), Mendoza (1977), Maitzen & Pavlovski (1987).

In 1966, Cameron (1966) defines a locus on the $[m_1]$ - $[c_1]$ diagram where the peculiar Ap stars are found. Later, Renson (1988) in his catalogue of Am and Ap stars in open clusters reports that some of the peculiar stars of Coma Berenices are Am stars. A compilation of some of the stars, known to belong to either category in the Coma Berenices cluster, is presented in Table 9. The relevant papers on spectroscopic classification include those of Trumpler (1938), Weaver (1952) and Mendoza (1963, 1967) as well as the compilations of Renson (1988) and Hoffleit & Jaschek (1981). From the photometric compilation carried out in the present paper and from the position of the stars in the $[m_1] - [c_1]$ diagram, several have been found to belong to the Ap class. These are listed in column 7 of Table 9.

It is worth mentioning that the status of the majority of these stars had been predicted by the previous work of Trumpler (1938), and the present analysis has served to support his assertions.

Since the abundance of Ap stars is interesting per se, it is worthwhile to mention that out of 26 A and F member stars, 4 have been found to belong to the Ap class, giving an Ap/(B+A+F) ratio of 0.154, although this figure has to be cautiously considered

since the absolute $uvby-\beta$ photometry in the Coma Berenices cluster compiled up to the present has not been exhaustive.

5.6 Variability

The variable stars in Coma Berenices observed and reported here have long been known to be variables. It is important to note that both HR 4684 and HD 106103 have been proved to be cluster members.

HR 4684 was first reported as a Delta Scuti star in 1968, but despite the long time span, very little had been done to study its periods of variability. Serendipitously, this star was observed almost simultaneously by the authors and by Paparo & Kovacs (1984). The period analysis of these three seasons has been already carried out and presented elsewhere (Paparo et al. 1993).

The physical characteristics of HR 4684 have been derived from uvby-β absolute photometry. These values were obtained in a separate observing season as indicated in Table 1. In this season, HR 4684 was observed for a time span of 40 minutes during which 10 data points in the uvby system were obtained. The transformation coefficients to the standard system will be reported elsewhere. The mean values obtained for V, b-y, m₁, c₁ are 6.460, 0.097, 0.188, 0.949 with standard deviations of 0.007, 0.002, 0.002, 0.005, respectively.

The photometric values obtained for HR 4684 are in agreement with those reported by Crawford & Barnes (1969), by Díaz (1991) or by López de Coca et al. (1990). Its physical characteristics can be determined from the previously described

^a Classifications reported in Trumpler 1938: Trumpler, Mount Wilson (W) and Victoria (V).

calibrations. The values determined are $\log g$ of 4.00 and T_{eff} of 8200 K. With these physical parameters, the period derived by Paparo et al. (1993) and the well known relation for the pulsation constant Q, one might conclude that this star is pulsating in the first overtone.

HD 106103 was established as variable in 1972, but much less information about it is available. The data obtained and presented here are insufficient to carry out an accurate period analysis of its periodic content, so the period of this star remains uncertain (López de Coca et al. 1990). With the reported value of the period, the physical parameters derived here, $\log g$ of 4.10 and T_{eff} of 6700 K, and which are in agreement with those of López de Coca et al. (1990), give an inconsistency in the PLCR; therefore new and more accurate data strings are needed to determine its period unequivocally.

6. SUMMARY AND CONCLUSIONS

New differential photometry of two Delta Scuti stars has been presented. The analysis of the periodic content of these photometric data and of other simultaneous campaigns have been presented elsewhere (Paparo et al. 1993). In order to derive the observational parameters of such variable stars $uvby-\beta$ photometry has been compiled from the literature (Crawford & Barnes 1969; Díaz 1991). Through this photometry these stars have been established as cluster members, with age and metal abundance determined. Physical parameters such as $\log g$ and $\log T_{eff}$ have been determined for both stars through direct comparison with theoretical models. As a by-product of the $uvby-\beta$ compilation of 69 stars in the direction of Coma Berenices some stars have been determined or corroborated as belonging to the Ap class.

The Mexican group would like to thank the staff of the Observatorio Astronómico Nacional for their assistance; CONACyT which, through grant DIII-903865, made the uvby- β observations possible; A. García, G. Ceron, and J.A. Miller for their assistance. JHP thanks the Academy of Sciences of Hungary for their support while at the Konkoly Observatory.
